

Checkbochs: Use Hardware to Check Software

Sorav Bansal

Abstract

In this paper, we present a system called Checkbochs, a machine simulator that checks rules about its guest operating system and applications at the hardware level. The properties to be checked can be implemented as ‘plugins’ in the Checkbochs simulator. Some of the properties that were checked using Checkbochs include null-pointer checks, format-string vulnerabilities, user/kernel pointer checks, and race-conditions. On implementing these checks, we were able to uncover previously-unknown bugs in widely used Linux distributions. We also tested our tools on undergraduate coursework, and found numerous bugs.

Software Reliability, Machine Simulation, Type Systems

I. INTRODUCTION

The use of software in many mission critical applications has led computer scientists to focus on software reliability, more than ever before. Many ways have been proposed to make software more reliable, secure and bug-free. Broadly, these techniques can be grouped into static compile-time techniques and dynamic run-time techniques.

Static compile-time techniques analyze program source code to detect errors. This method, though very effective cannot take advantage of the information available at run-time. Dynamic runtime techniques on the other hand mostly rely on an interpreted environment, or instrumentation at source-code or binary level. For this reason, dynamic runtime techniques have seldom been used to test the correctness of an operating system. Instrumenting the source code or binary of an operating system requires clever engineering effort and deep understanding of the OS internals. Further, binary instrumentation requires thorough understanding of the instruction set architecture. And even when the instrumentation is complete and correct, the execution of instrumented code can change the behavior of the OS indeterministically due to a different interleaving of concurrent threads.

In this paper, we present a dynamic runtime checker called Checkbochs which has been implemented using an existing x86 machine simulator called Bochs [5]. Since each machine instruction in a simulator is interpreted, it allows us to do complex runtime analyses without the pitfalls associated with instrumentation. By tracking data flow at runtime, and checking for some known properties, we found interesting bugs in two widely used Linux distributions. We also implemented a dynamic data race detector inside the simulator to be able to find data races in operating systems. As a case study, we checked an academic operating system called Pintos which was built as part of undergraduate coursework at Stanford.

Some of our contributions are:

- Checkbochs allows dynamic runtime analysis by implementing rules to be executed while interpreting instructions in the guest software.
- Checkbochs can identify bugs across all layers of software running on the system. It does not require prior knowledge of the applications or their source code before reporting violations.

- Checkbochs does not change application or OS behavior in any way since all its operations occur at the hardware level. In fact, Checkbochs can be used on an existing disk image.
- Implementing new runtime rules in Checkbochs is easy and straightforward

This paper is organized as follows. Section II explains the Checkbochs dataflow analysis framework that can be extended to check various system rules at runtime. Section III describes the implementation of one such rule - the dynamic data race detector. Section IV discusses the related work, and finally Section V concludes.

II. DYNAMIC DATA FLOW ANALYSIS

In our dynamic data flow analyses, we wish to infer types of machine values and then check for violations of type-properties at runtime. For example, if two file-descriptors are multiplied at any point in the execution of the system, it signals an error.

Checkbochs provides a framework, which allows users to specify data types and corresponding system rules to be checked during runtime. In this section, we describe the implementation of this framework and also the results obtained by implementing some rules.

A. Implementation

To track types of machine values, Checkbochs maintains a *shadow machine state*. The shadow state consists of the shadow registers, instructions and shadow physical memory. Since the instructions use virtual memory addresses, we also implemented a virtual-memory translation logic in the shadow space.

Data flow is monitored by associating all data transfer and arithmetic instructions (*load*, *store*, *move*, *add*, etc.) with their counterparts in shadow space. For example, a *move dest, src* instruction would also cause the contents of *src* to be copied to *dest* in shadow space. Using this data flow framework, we tag data values with their *types* in shadow space and analyse their flow across the system. Some of the types that we inferred using Checkbochs are tabulated in Table II-A with their method of inference.

Method Of Inference	Types
Linux System Call Interface	User Pointers, File Descriptors, Strings
x86 Instruction Operands	I/O address, I/O bytes, NullChecked, Memory Address, Code/Data
Planted Shadow Instructions in Guest Software	malloc/fopen return value, user pointer safety

TABLE I
TYPE VALUES AND THEIR METHOD OF INFERENCE AT THE
HARDWARE LEVEL

Sometimes, the flow of type information is not directly associated with the corresponding data flow. For example, consider the sample code of the `read()` system call in Figure 1. At the entry of the function, `buf` is an *unchecked user*

```

ssize_t sys_read(...,char *buf,...) {
    char *tmp = buf;
    if (!access_ok(tmp)) fail();
    ...
    *buf = 42; /* safe? */
}

```

Fig. 1. The system call parameter `buf` is an unsafe user pointer. However, since a derived variable `tmp` has been checked for safety, the assignment to `*buf` should be considered legal.

pointer. The assignment statement `tmp=buf` changes the type of `tmp` to an unsafe user pointer too. Subsequently, `tmp` goes through the appropriate check and its type is changed to a safe user pointer. However, the result of this check is not reflected on the type of `buf` and the line `*buf=42` will incorrectly flag a warning.

We solved this problem by using an extra level of indirection in the shadow space. Instead of holding the type value, the shadow state holds pointers to type objects. Hence, an assignment statement like `tmp=buf` causes the pointer to `buf`'s type object to be copied to `tmp`'s shadow state. Since both `buf` and `tmp` now point to the same type object, any change in `tmp`'s type is reflected in `buf`'s type and vice versa. This extra level of indirection is also illustrated in Figure 2

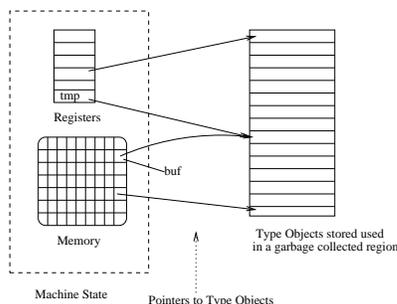

Fig. 2. **Pointers to Type Objects.** Both `tmp` and `buf` point to the same type object, after assignment of `tmp` to `buf`. Hence, any change to the type of `tmp` will also reflect in the type of `buf`.

B. Results

We ran two different disk images on Checkbochs: `debian-3.0r1` and `gentoo-2004.3`. Both these disk

images were obtained after freshly installing the latest available distribution CDs by these vendors. Using our dataflow framework, we check for flavors of `copyin/copyout` bugs, improper handling of `malloc()`, `fopen()` functions and `formatstring` vulnerabilities. The results obtained by performing these checks are described in detail in the following sections.

1) *CopyIn/CopyOut Bugs*: A user value passed as a system call argument must be checked through one of the `copyin/copyout` functions before getting dereferenced. Failure to do so, opens a port of attack, whereby an attacker can crash the kernel, or worse be able to write his own data at a specific kernel address. Another variation of this rule is that a user pointer should never be dereferenced in the kernel with disabled interrupts.

Implementing this rule using our data flow framework was straightforward. All system call parameters are tagged as *unchecked user values*. Any check on the user value through one of the `copyin/copyout` functions cause the type of the user value to change from *unchecked* to *checked user value*. A warning is flagged if an unchecked user value is dereferenced in the kernel or a user value is dereferenced with disabled interrupts.

Using these rules, we identified one `copyin/copyout` bug in the `poll` system call of the linux kernel. In this instance, the user pointer was checked for read access, while a write operation was performed on it. This can be a security flaw on many architectures, including Intel 386. The submitted bug was acknowledged by Alan Cox on the Linux Kernel Mailing List [9].

2) *Improper handling of malloc(), fopen() return values*: Any use of `glibc` functions like `malloc()` and `fopen()` must be accompanied by a null check before they are used. To check this rule, we tagged the return values of these functions until they were checked against `null`. Implementing this rule, we found many instances of violation in the kernel and common applications like `ps`, `grep`, `fsck`, and `swapon`. The violations in the kernel were found in the IDE device driver of `linux-2.4.18`. In all, after minimal testing, we found 16 bugs in user-level software and 6 bugs in the kernel. All these bugs were accepted, and subsequently fixed.

3) *Formatstring Vulnerabilities*: A `formatstring` vulnerability [8] is caused due to a design misfeature in the C standard library combined with problematic implementation of variable argument functions. A value from an untrusted source (such as the network) should not be used without proper checks inside the `formatstring` argument of the `printf` family of functions. Failure to do so, can lead to a complete compromise of security, when combined with other bugs. To test applications, we mounted an NFS partition on the guest system and ran a number of applications on it. Although, we hoped to obtain some bugs in applications running on data in the untrusted NFS partition, we obtained only one false positive in the `sendmail` program. In this

Rule	Kernel Bugs	Application Bugs	False Positives
Pointers/File Descriptors checked against NULL	6	16	0
CopyIn/CopyOut Bugs	1	-	4
Untrusted IO in FormatString	0	0	1

Fig. 3. **Summary:** The table summarizes the results obtained on implementing certain rules and checking two widely used Linux distributions. Besides these rules, we implemented the race-detection algorithm in Checkbochs which uncovered numerous bugs in undergraduate coursework.

case, each character of the string received over the network was carefully checked before using it in the formatstring. Since our rule does not implement a way of finding out whether a value has been appropriately checked for safety, it reports a false warning.

In essence, we believe that machine simulation allows us to track data flow across many different applications, which would have been difficult (if not impossible) to do with instrumentation techniques. We are investigating other uses of this dataflow framework in determining interesting system properties. Recently, dynamic dataflow tracing was used to determine lifetime of sensitive data like passwords [6]. The work revealed the startling result that sensitive information could live in the system for a long time in places like system caches and device buffers (places which are not in the control of the application vendor).

III. RACE CONDITIONS

Multi-threaded programming is difficult and error-prone. It is easy to make a mistake that produces a data race, yet it can be extremely hard to locate this mistake during debugging. A very effective dynamic data race detection algorithm is the lockset algorithm, first proposed in a tool called Eraser [16]. Eraser used binary rewriting techniques to monitor every shared memory reference and verify that consistent locking behavior is observed. The lockset algorithm enforces the simple locking discipline that every shared variable is protected by some lock. Since there is no way of knowing which locks are intended to protect which variables, this protection relation can be inferred from the execution history. Figure 4 summarizes the lockset algorithm. More details on the algorithm can be found at [16].

We implemented the lockset algorithm in Checkbochs. On testing undergraduate coursework [12], we found numerous bugs in assignments that had received a near-perfect score. We also found one benign race in the base operating system `pintos` [13] provided to the students.

Let $locks_held(t)$ be the set of locks held by thread t
 For each v , initialize $lockset(v)$ to the set of all locks
 On each access to v by thread t ,
 set $lockset(v) := lockset(v) \cap locks - held(t)$;
 if $C(v) = \{\}$, then issue a warning.

Fig. 4. **The Lockset Algorithm**

IV. RELATED WORK

There has been a growing impetus on software reliability and security in recent years. Researchers have considered many ways to perform post-production checks in software.

Static compile-time analysis with programmer written compiler-extensions was used to catch around 500 bugs in the linux kernel [1], [2]. Using static data flow analysis and domain specific knowledge, many bugs were found in the heavily audited kernel. Ways have also been suggested to automatically detect anomalies as deviant behavior in the source code [3]. Most of the bugs checked by static analysis are local to a single file, sometimes even local to a single procedure. This is due to the complexity involved in performing global compile time analysis. This limits the power of static analysis tools to *surface bugs*. Our approach, on the other hand, can track data flow across many different software components possibly written by different vendors and can thus target a different variety of errors. However, static analysis has the huge advantage of being able to check all possible code paths, while our execution-driven approach can only check bugs along the path of execution in the system.

Recently, model checking was used to find serious file system errors [4]. Using an abstract model and intelligent reduction of the state space, they could check for errors which would have required an exponential number of search paths through traditional testing. Model checking can check for deeper semantic bugs than possible with static compile-time analysis. We intend to use similar ideas to model check entire system images, thus allowing us to search a larger number of execution paths while performing our shadow machine analysis. One of the obstacles in this direction is the slow speed of machine simulation that makes execution of speculative paths almost infeasible.

Shadow machine simulation has been previously used to perform taint analysis to determine the data lifetime of sensitive data [6]. This work reported a startling observation that sensitive data like passwords and credit card numbers may reside in computer's memory and disk long after the user has logged out. Such leaks occur at caches, I/O buffers, kernel queues, and other places which are not under the control of the application developer. Our work uses a similar taint analysis by marking all bytes received over the network as untrusted and checking if they are used in unwanted ways (eg. formatstring).

Recently, [15] used taint-analysis on untrusted data to check for security violations such as buffer overflows and formatstring attacks in applications. By implementing a valgrind skin, they were able to restrict the overhead of their taint-analysis tool to 10-25x. Considering that the computation power is relatively cheap, they suggest using their tool in production

runs of the software. This will detect and prevent any online attacks on the system.

V. CONCLUSION

We present a novel technique to finding bugs and security holes in system software. Our technique can check for bugs across all layers of software, from the OS to the application. Our approach has very low false positive and false negative rates. This technique can be especially very useful in expediting the process of discovering bugs during software testing.

We conjecture that shadow machine simulation, combined with speculative execution (such as model-checking) can yield a huge number of bugs. While the slow speed of machine simulation is an impediment to this approach, we are considering using virtual machine environments to achieve the same objective.

VI. ACKNOWLEDGEMENTS

This work was done under the able guidance and support from Mendel Rosenblum, Professor of Computer Science, Stanford University. The author would also like to thank Ben Pfaff for very insightful discussions, help with testing Checkbochs on pintos, and making Checkbochs available to CS140 students.
